Regression Discontinuity: Starting Point

We want to **estimate a treatment effect**, but there is likely **selection bias**.

The required assumption

$$E[Y_{0i}|D_i = 1] - E[Y_{0i}|D_i = 0] = 0$$

does not hold.

RD exploits settings where this assumption often holds

- ▶ arbitrary thresholds that determine treatment assignment
- ▶ typically regulatory thresholds
- ▶ Probability of treatment “jumps” at the discontinuity

Regression Discontinuity

Examples for discontinuities

- ▶ Income thresholds for social benefits
- ▶ Cutoff rules for class sizes
- ▶ GPA thresholds for getting into college
- ▶ Special treatment for babies with $<1500\text{g}$ birth weight
- ▶ ...

Basic idea

- ▶ At the threshold, the **probability of treatment changes** sharply
- ▶ But **nothing else changes**
- ▶ Being **above or below** the threshold is **as good as random**

RD lingo

The forcing variable X

- ▶ The **variable that determines treatment assignment**
- ▶ Also called assignment or running variable

The discontinuity X_0

- ▶ threshold value of the running variable at which treatment assignment jumps

Example of a linear RD

The aim is to estimate the **treatment effect** (here τ) **at the discontinuity**

RDD in a DAG

(A) Data generating graph

(B) Limiting graph

The **running variable X** determines the treatment D

Left: X may also affect the outcome through U

Right: Being above or below the threshold c_0 is as good as random

Sharp and Fuzzy Regression Discontinuity

Sharp RDD: treatment probability jumps at X_0 from 0 to 1

Fuzzy RDD: treatment probability jumps at X_0

Example of a Sharp RDD: Carpenter & Dobkin (2009)

Observation: there is a **spike in deaths around the 21st birthday**

... but no difference around the 20th or 22nd birthday

Example of a Sharp RDD: Carpenter & Dobkin (2009)

Carpenter & Dobkin (2009) investigate if this spike is **due to the legal drinking age** (21 in US)

Idea: at 21, nothing changes except that people can drink legally

Sharp RD: age is the running variable

$$D_a = \begin{cases} 1, & \text{if } a \geq 21. \\ 0, & \text{if } a < 21. \end{cases}$$

Treatment status is a **deterministic function of the running variable**

- if we know a , we know D_a

Example of a Sharp RDD: Carpenter & Dobkin (2009)

Simple RD analysis in a regression framework

$$\text{death rate}_a = \alpha + \rho D_a + \gamma a + e_a$$

Example of a Sharp RDD: Carpenter & Dobkin (2009)

Does the **jump in the death rate ρ** represent a causal effect?

Yes if D_a is solely determined by a

- ▶ This is plausible in the given setting
- ▶ in this case there is no omitted variable bias
- ▶ no need to control for anything

Advantage of RDs: they are credible and transparent

Downside of RDs: they estimate local effects; difficult to extrapolate

Example of a Fuzzey RDD: Hoekstra (2009)

Question: what is the impact of attending a State flagship university on earnings?

Background: many U.S. states have flagship universities

- ▶ Examples: University of Virginia, University of Florida, University of Michigan
- ▶ Is **going to University of Florida better** than going to **University of Southern Florida**?

Challenge: it is not random who goes to a particular university

Example of a Fuzzey RDD: Hoekstra (2009)

Identification strategy: Hoekstra exploits admission cutoffs in a fuzzy RD design

- ▶ Applicants need a certain SAT score to be admitted
- ▶ The design is fuzzy because not everyone with a high SAT score applies and enrolls

Identification assumption: students cannot manipulate whether they are above or below the cutoff

Data used in Hoekstra (2009)

Administrative records from a large **flagship university** (not disclosed which one)

- ▶ Includes data on all applicants, including their SAT scores

Social Security Administration (SSA) data on earnings

First stage: SAT vs enrolment

Binscatter of SAT scores and enrolment rates

Reduced form: SAT vs log earnings

Binscatter of SAT scores and enrolment rates

Lessons from Hoekstra (2009)

Being **above the cutoff increases**

- ▶ the probability of enrolling by close to 40 percentage points
- ▶ earnings by around 10 percent

We can **calculate the LATE**: $\frac{0.1}{0.4} \times 100\% = 25\%$

Sharp RD: Formal Derivation Angrist & Pischke (2009, ch. 6)

Treatment status D_i is a deterministic function of x_i with a **discontinuity** at x_0

$$D_i = \begin{cases} 1 & \text{if } x_i \geq x_0 \\ 0 & \text{if } x_i < x_0 \end{cases}$$

Assume a **constant effects model**

$$\begin{aligned} E[Y_{0i}|x_i] &= \alpha + \beta x_i \\ Y_{1i} &= Y_{0i} + \rho \end{aligned}$$

Sharp RD: Formal Derivation (Angrist & Pischke 2009, Ch.6)

The **corresponding regression** is

$$Y_i = \alpha + \beta x_i + \rho D_i + \eta_i$$

Of if the trend relation $E[Y_{0i}|x_i]$ is **non-linear**:

$$Y_i = \alpha + f(x_i) + \rho D_i + \eta_i$$

$f(x_i)$ modeled as a **p-th order polynomial**

$$Y_i = \alpha + \beta_1 x_i + \beta_2 x_i^2 + \dots + \beta_p x_i^p + \rho D_i + \eta_i$$

Sharp RD: Formal Derivation (Angrist & Pischke 2009, Ch.6)

Or allowing for **separate trend functions** for treated and untreated observations

$$E[Y_{0i}|x_i] = f_0(x_i) = \alpha + \beta_{01}\tilde{x}_i + \beta_{02}\tilde{x}_i^2 + \dots + \beta_{0p}\tilde{x}_i^p$$

$$E[Y_{1i}|x_i] = f_1(x_i) = \alpha + \rho + \beta_{11}\tilde{x}_i + \beta_{12}\tilde{x}_i^2 + \dots + \beta_{1p}\tilde{x}_i^p$$

with $\tilde{x}_i \equiv x_i - x_0$

Use the fact that D_i is a deterministic function of x_i

$$E[Y_i|x_i] = E[Y_{0i}|x_i] + E[Y_{1i} - Y_{0i}|x_i] D_i$$

Sharp RD: Formal Derivation (Angrist & Pischke 2009, Ch.6)

Substituting polynomials for conditional expectations yields the regression

$$Y_i = \alpha + \beta_{01}\tilde{x}_i + \beta_{02}\tilde{x}_i^2 + \dots + \beta_{0p}\tilde{x}_i^p \\ + \rho D_i + \beta_1^* D_i \tilde{x}_i + \beta_2^* D_i \tilde{x}_i^2 + \dots + \beta_p^* D_i \tilde{x}_i^p + \eta_i$$

If we want to restrict the sample to a **bandwidth** δ

$$E[Y_i | x_0 - \delta < x_i < x_0] \simeq E[Y_{0i} | x_i = x_0] \\ E[Y_i | x_0 < x_i < x_0 + \delta] \simeq E[Y_{1i} | x_i = x_0]$$

... the **estimand becomes**

$$\lim_{\delta \rightarrow 0} E[Y_i | x_0 < x_i < x_0 + \delta] - E[Y_i | x_0 - \delta < x_i < x_0] = E[Y_{1i} - Y_{0i} | x_i = x_0]$$

Extrapolation in a Sharp RD

The RDD does not have common support

- ▶ Units above the cutoff are treated $D_i = 1$
- ▶ Units below the cutoff are untreated $D_i = 0$

The Continuity Assumption

The **continuity assumption** is the key identifying assumption in the RD design

- ▶ It states that the potential outcomes are continuous functions of the running variable X
- ▶ $E[Y_i^0 \mid X = x_0] = E[Y_i^1 \mid X = x_0]$

What does continuity mean?

- ▶ potential outcomes don't jump at the cutoff
- ▶ there are no competing interventions
- ▶ people don't select into being above or below the cutoff

RD: Importance of Functional Form

RDs don't guarantee the estimation of a **causal effect**

Problem: what looks like a discontinuous jump may actually be an **increase in a non-linear function**

It is important to

- ▶ **distinguish** between a **true causal effect** and an increase in a **non-linear trend**
- ▶ assess (and model) the **functional form** between the running variable and the outcome

RD: Importance of Functional Form

Linear vs. quadratic function

RD: Importance of Functional Form

Example of a spurious jump

In an RD paper, it is important to show the **robustness of the results** to the choice of **functional form**

RD: Importance of Functional Form

We can capture the curvature by including a quadratic in age

$$\text{death rate}_a = \alpha + \rho D_a + \gamma_1 a + \gamma_2 a^2 + e_a$$

Problem: often the **slope or curvature differs above and below the cutoff**

For example, below 21-year-olds are subject to minimum drinking age laws

RD: Importance of Functional Form

Two measures solve this problem

- ▶ center the running variable around the cutoff (i.e. use $a - a_0$)
- ▶ add an interaction term $(a - a_0)D_a$

$$\text{death rate}_a = \alpha + \rho D_a + \gamma(a - a_0) + \delta[(a - a_0)D_a] + e_a$$

This equation still identifies the effect at the cutoff ($a = a_0$)

RD: Importance of Functional Form

It is also possible to fit a **polynomial on either side of the cut-off**

$$\begin{aligned}\text{death rate}_a &= \alpha + \rho D_a + \gamma_1(a - a_0) + \gamma_2(a - a_0)^2 \\ &+ \delta_1[(a - a_0)D_a] + \delta_2[(a - a_0)^2 D_a] + e_a\end{aligned}$$

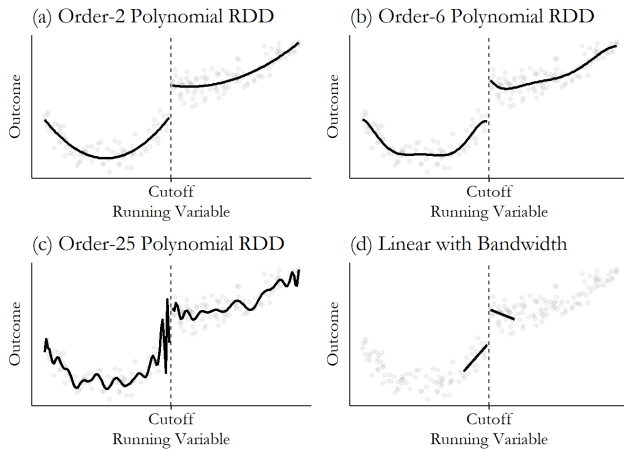

RD: Importance of Functional Form

Linear vs quadratic functional form in Carpenter & Dobkin (2009)

Treatment effect is larger with quadratic controls

RD: Importance of Functional Form

Source: Huntington-Klein, The Effect

Overfitting? Crimes against Data?

Gelman & Imbens (2019): polynomials can lead to **overfitting**

The plotted line reports the fitted values from a regression of life expectancy on a cubic in latitude using the sample of DSP locations, weighted by the population at each location.

Overfitting? Crimes against Data?

Overfitting

- ▶ There is often **no scientific reason** to have high-order **polynomials**
- ▶ Overfitting: parameter estimates rely on **too few data points**
- ▶ **Large weights** are given to observations **far away from the discontinuity**
- ▶ Genuine **uncertainty** from model dependence is **not reflected in standard errors**

More on overfitting in RDs: Green *et al.* (2009), Gelman & Imbens (2019)

Bandwidth Selection

One method to reduce the likelihood of spurious effects is to **narrow the bandwidth**

The bandwidth is the **“window” below and above the cutoff**

Idea:

- ▶ The closer we “zoom in” on the cutoff
- ▶ ... the lower is the chance of picking up a trend

Bandwidth Selection

Trade-off in bandwidth selection

- ▶ smaller bandwidth \Rightarrow **smaller bias**
- ▶ smaller bandwidth \Rightarrow **less precision**

The graph on the following page illustrates **two common methods**

- ▶ (non-parametric) kernel density estimation
- ▶ local linear regressions

Optimal bandwidth selection is a very active area of research in econometrics. See, for example, Imbens & Kalyanaraman (2012).

Bandwidth Selection

Bandwidth Selection: Practical Advice

In a typical RDD paper you will see a **variety of bandwidths**

The preferred bandwidth in many studies is the **optimal bandwidth from Calonico *et al.* (2014)**

- ▶ It trades off bias and variance
- ▶ the `rdrobust` package in R implements this method

Local Regression

Simplest form: **compare means above and below** within bandwidth

- ▶ Problem: differential trends in Y above and below can lead to bias

Alternatives:

- ▶ Local linear regression
- ▶ Kernel regression

Local Linear Regression

Simple **local linear regression restricts the sample to** $a_0 - b \leq a \leq a_0 + b$

And estimates a linear regression in this window:

$$\text{death rate}_a = \alpha + \rho D_a + \gamma a + e_a$$

Or, more commonly, we can **allow for different slopes above and below the cut-off**

Kernel Regression

Assign weights that

- ▶ are maximized at the cutoff
- ▶ are zero outside the bandwidth

Example for **triangular kernel**

Fuzzy RDD

In a fuzzy RDD, the **probability of treatment jumps at the cutoff**

$$P[D_i = 1|x_i] = \begin{cases} g_1(x_i), & \text{if } x_i \geq x_0. \\ g_0(x_i), & \text{if } x_i < x_0. \end{cases}$$

where $g_1(x_0) \neq g_0(x_0)$

This set-up is **equivalent to an IV estimator**

- ▶ The discontinuity is the instrument for the treatment
- ▶ If we control for the forcing variable, the assignment of the IV is as good as random

Fuzzy RDD

Simplest case: let T_i be the discontinuity and D_i be the treatment

The (hypothetical) **first stage** is

$$D_i = \gamma_0 + \gamma_1 X_i + \gamma_2 T_i + e_i$$

But because we often don't observe the treatment, we **estimate the reduced form**

$$y_i = \alpha + \beta T_i + \delta X_i + u_i$$

Fuzzy RDD

Wald Estimator with a bandwidth of δ

$$\lim_{\delta \rightarrow 0} \frac{E[Y_i | x_0 < x_i < x_0 + \delta] - E[Y_i | x_0 - \delta < x_i < x_0]}{E[D_i | x_0 < x_i < x_0 + \delta] - E[D_i | x_0 - \delta < x_i < x_0]} = \rho$$

Fuzzy RDD

Fuzzy RD becomes **more tricky with interactions** (treatment with forcing variable)

⇒ need a **separate IV and first stage** for each term including D_i

This means that one has as **many instruments** as there are terms including D_i

Rather than deriving this, we will look at an example: Angrist & Lavy (1999)

Fuzzy RD: Angrist & Lavy (1999)

Angrist & Lavy (1999) study the **impact of class sizes on student achievement**

They exploit that **class sizes in Israeli schools follow Maimonides' rule**

- ▶ Class size is capped at 40
- ▶ If enrollment reaches 41, two classes are formed
- ▶ Three classes are formed if the enrollment reaches 80, etc

Fuzzy RD: Angrist & Lavy (1999)

Fuzzy RD: Angrist & Lavy (1999)

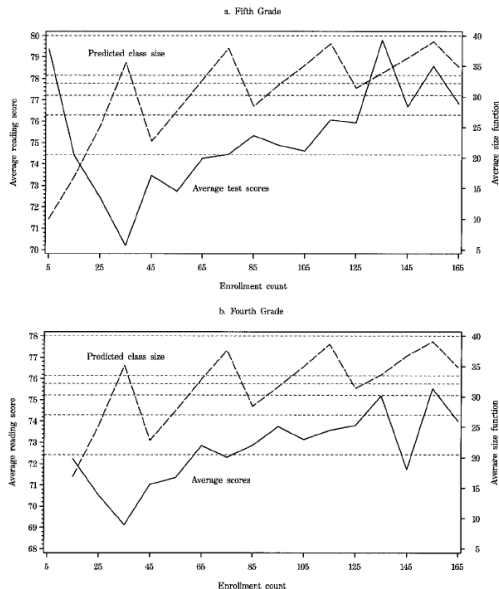

Angrist & Lavy (1999) use the **predicted class size as instrument for the actual class size**

Prediction is based on a mathematical formula (namely Maimonides' rule)

Not all **schools fully comply, but most do**

This is a **classic example of a fuzzy RD**

Fuzzy RD: Angrist & Lavy (1999)

Fuzzy RD: Angrist & Lavy (1999)

| Enrollment | | .022 (.009) | .012 (.026) | | | .053 (.028) | | .041 (.012) | .062 (.037) | | | .079 (.036) |
| Enrollment squared/100 | | | .005 (.011) | | | | | | -.010 (.016) | | | |
| Piecewise linear trend | | | | .136 (.032) | | | | | | .193 (.040) | | |
| Root MSE | 6.15 | 6.23 | 6.22 | 7.71 | 6.79 | 7.15 | 8.34 | 8.40 | 8.42 | 9.49 | 8.79 | 9.10 |
| N | | 2019 | | 1961 | | 471 | | 2018 | | 1960 | | 471 |

The unit of observation is the average score in the class. Standard errors are reported in parentheses. Standard errors were corrected for within-school correlation between classes. All estimates use f_{sc} as an instrument for class size.

Fuzzy RD: Angrist & Lavy (1999)

- ▶ Table II shows **OLS estimates**: There is a positive correlation between class size and test scores in the raw data. This correlation vanishes when the fraction of disadvantaged students is controlled for.
- ▶ Table IV shows the **IV results**, exploiting the regression discontinuities created by Maimonides' rule. The table displays various specifications with no, linear, quadratic, and piecewise linear controls for enrollment, as well as estimates in subsamples around the discontinuity points.

Fuzzy RD: Angrist & Lavy (1999)

- ▶ **Controlling for enrollment is important**, particularly for the math test scores. The form of the control matters less.
- ▶ On the other hand, the **discontinuity samples give larger effects** (in absolute values) than the full sample, which is less comforting.
- ▶ Overall, they find that the IV estimates are larger than the OLS estimates.
- ▶ The **downward bias of OLS** is plausible as it may be the case that poorer performing students are placed in smaller classes.

Regression Discontinuity: Comments

Regression Discontinuity has become one of **the most popular methods of causal inference**

Some reasons:

- ▶ It's easy to explain to non-economists
- ▶ The researcher is forced to show patterns in the data
- ▶ Identification assumptions can be inspected graphically
- ▶ It is often clear what drives the variation in the treatment

For useful practitioners' guides, see Matias Cattaneo (Michigan) and David Lee (Princeton)

Challenge to Identification

As with any method of causal inference, RD rests on an **untestable identification assumption**

- ▶ being **above or below the cutoff** is as good as random

This may not be true if there is **manipulation**

- ▶ people may be able to choose whether they are above or below the cutoff
- ▶ teachers may grade people up, etc

Example for Manipulation

What Can/Should You Do?

There are **non-parametric tests** for heaping/bunching

- ▶ McCrary density test (McCrary, 2008)

Run placebo tests based on pre-treatment characteristics

- ▶ there should be no jump at the discontinuity
- ▶ if there is, that's a problem

One solution: a donut hole estimator (leave out points close to the discontinuity)

RD: The Cookbook

3 General Rules: plot, plot, plot!

1) Explain the Identification Strategy

- ▶ why is there a discontinuity?
- ▶ and what is the treatment that changes?
- ▶ what is the scope for manipulation?

2) Produce and discuss the main graph

- ▶ Outcome plotted against the running variable
- ▶ Best to use binned scatters
- ▶ Important to find the right functional form
- ▶ Use practitioners' guides, for example Lee & Lemieux (2010)

RD: The Cookbook

{Source: Lee & Lemieux (2010)}

RD: The Cookbook

{Source: Lee & Lemieux (2010)}

RD: The Cookbook

3) Report estimates based on different methods

- ▶ careful when using polynomials
- ▶ local linear regression
- ▶ kernel methods

4) Density and placebo tests

- ▶ Inspect if there is heaping at the discontinuity
- ▶ Run a McCrary density test
- ▶ Plot pre-treatment characteristics against the running variable
- ▶ Check out the latest literature. If you don't run the latest tests, your referees will ask you to (If you're lucky)...

RD: The Cookbook

{Source: Lee & Lemieux (2010)}

Appendix

RDD in R

The following slides show how an RDD can be implemented with R. Most of this code is from Cunningham's Mixtape and Huntington-Klein's Effect.

You need the following packages: `tidyverse`, `stargazer`, `causaldata`, and `rdrobust` and `rddensity`.

We first simulate a dataset and then show how we run regressions.

RDD in R – Simulated Dataset

```
# simulate the data
dat <- tibble(
  x = rnorm(1000, 50, 25)
) %>%
  mutate(
    x = if_else(x < 0, 0, x)
  ) %>%
  filter(x < 100)

# cutoff at x = 50
dat <- dat %>%
  mutate(
    D = if_else(x > 50, 1, 0),
    y1 = 25 + 0 * D + 1.5 * x + rnorm(n(), 0, 20)
  )
```

RDD in R – RDD plot with ggplot

```
# Simulate data with discontinuity
dat <- dat %>%
  mutate(
    y2 = 25 + 40 * D + 1.5 * x + rnorm(n(), 0, 20)
  )

# Plot
ggplot(aes(x, y2, colour = factor(D)), data = dat) +
  geom_point(alpha = 0.5) +
  geom_vline(xintercept = 50, colour = "grey", linetype = 2) +
  stat_smooth(method = "lm", se = F) +
  theme_minimal() +
  theme(text = element_text(size = 20), legend.position = "none") +
  labs(x = "Test score (X)", y = "Potential Outcome (Y)")
```

The code from the previous slide gives this

RDD Regressions in R

The regressions are based on the package `causaldata`, which has data on a government transfer that was administered based on an income cutoff. The original study was done by Manacorda et al (2011).

RDD Regressions in R

Data preparation next slide

- ▶ binned data for bin scatter
- ▶ add kernel weights

RDD Regressions in R

```
gt <- causaldata::gov_transfers

# Use cut() to create bins, using breaks to make sure it breaks at 0
# (-15:15)*.02/15 gives 15 breaks from -.02 to .02
binned <- gt %>%
  mutate(Inc_Bins = cut(Income_Centered,
                        breaks = (-15:15)*(.02/15))) %>%
  group_by(Inc_Bins) %>%
  summarize(Support = mean(Support),
            Income = mean(Income_Centered))

# Add a triangular kernel weight
kweight <- function(x) {
  # To start at a weight of 0 at x = 0, and impose a bandwidth of .01,
  # we need a "slope" of  $-1/.01 = 100$ ,
  # and to go in either direction use the absolute value
  w <- 1 - 100*abs(x)
  # if further away than .01, the weight is 0, not negative
  w <- ifelse(w < 0, 0, w)
  return(w)
}

gt <- gt |> mutate(kweight=kweight(Income_Centered))
```

RDD Regressions in R

Binned scatter

```
# Taking the mean of Income lets us plot  
# data roughly at the bin midpoints  
  
ggplot(binned, aes(x = Income, y = Support)) +  
  geom_point(size=5) +  
  theme_minimal() +  
  theme(text = element_text(size = 20)) +  
  # Add a cutoff line  
  geom_vline(aes(xintercept = 0), linetype = 'dashed')
```

RDD Regressions in R

```
# Reg 1: linear term
m1 <- lm(Support ~ Income_Centered*Participation, data = gt)

# Reg 2: model with square
m2 <- lm(Support ~ Income_Centered*Participation +
         I(Income_Centered^2)*Participation, data = gt)

# Reg 3: model with Kernel weights
m3 <- lm(Support ~ Income_Centered*Participation, data = gt,
         weights = kweight)

# Regression results:

stargazer(m1, m2, m3, header=FALSE, type='latex', font.size="tiny",
          single.row=TRUE)
```

Table 1:

| | <i>Dependent variable:</i> | | |
|------------------------------------|----------------------------|--------------------------------|-------------------------|
| | Support | | |
| | (1) | (2) | (3) |
| Income_Centered | −0.179 (1.916) | −11.567 (7.777) | −23.697*** (6.430) |

RDD Regressions in R

On the previous slide we can see that

- ▶ The estimated **treatment effect is large** when we fit linear or quadratic **regressions** (9.3pp, statistically significant)
- ▶ But it is **small** when we fit a **triangular Kernel regression**

Note: the Kernel regression uses a lot fewer observations (bias-variance trade-off...)

Using rdrobust

`rdrobust` is a very useful package because it has many useful in-built functions

- ▶ generates **RD plots**
- ▶ allows for **optimal bandwidth selection**
- ▶ allows for **fuzzy RDD**

Using rdrobust

```
# Estimate regression discontinuity and plot it  
m <- rdrobust(gt$Support, gt$Income_Centered, c = 0, p=1)  
summary(m)
```

```
# Note, by default, rdrobust and rdplot use different numbers  
# of polynomial terms. You can set the p option to standardize them.  
rdplot(gt$Support, gt$Income_Centered, masspoints="off", p=1)
```

Nice feature: can change the order of polynomial through the p option

Not so nice feature: hard to change the layout of the plot

RD Plot

Density test with rddensity

```
gt <- causaldata::gov_transfers_density %>%  
  filter(abs(Income_Centered) < .02)  
  
# Estimate the discontinuity  
gt %>%  
  pull(Income_Centered) %>%  
  rddensity(c = 0) %>%  
  summary()
```
